

Lec 8: Observational vs Experimental Studies

Corinne Riddell

September 12, 2022

Important Note

There are several definitions and descriptions in the book chapter that I disagree with or think are poorly described. Particularly in Edition 4:

- pg 142: Observation vs. Experiment textbox and following paragraph
- pg 143: Definition of confounding and conceptual diagram of confounding
- pg 147: Description of bias

For the concepts around sampling and observational studies and study design in general, for these sections, and for the definitions of causality and confounding, **the material presented in lecture takes precedence**

Learning objectives for today

Defining a study by:

- Whether the treatment or exposure is controlled by an investigator
 - Experimental vs observational designs
- The population of interest
 - Target population
 - Study population
 - Study sample
- How the sample was drawn from the population
 - Complete sample (census)
 - Random sampling
 - Convenience sampling
 - Volunteer sampling
- Method and timing of data collection

Types of problems: from our PPDAC framework

- Recall the three types of studies we conduct:
 - Descriptive
 - Predictive
 - Causative/Etiologic

- The book argues that experiments are “the only source of fully convincing data” to study causes and effect. However, epidemiologists, sociologists, political scientists, economists, and others use observational data to study cause and effect and have developed a careful theory of causal inference that this textbook doesn’t consider. These studies can be used to study cause and effect, just think of some of the most compelling examples like the effect of smoking on lung cancer, or the effect of HPV on cervical cancer.

Observation vs. Experimentation

- A study is observational if the researcher **observes** what happens and does not control who is treated or exposed.
- A study is experimental if the investigator is **experimenting** (or intervening) by controlling who is treated or exposed.
- In an experimental study, the exposure is assigned by a randomization mechanism that is controlled by the investigator

Observation vs. Experimentation

- To support their point that observational data cannot be trusted, Baldi & Moore present an example of observational data being misleading. In the example, researchers study the causal effect of hormone replacement therapy on cardiovascular disease. However, these observational data, analysed in a different way yield the same conclusion as the experimental study (the randomized controlled trial). Here is a link to the reanalysis of these data: [link](#).
- To summarize, experimental studies are great because you can randomize who receives treatment and who does not. This reduces bias (especially confounding) and should be used when it is ethical to conduct an experiment, like all the studies conducted on preventing covid (randomized clinical trials of vaccines) or treatment of covid.
- Not all exposures of interest can be randomized because it is not ethical. In this case, we are left with observational data. Not all observational data is the same – we can conduct clever studies to reduce or eliminate certain types of bias and analyze the data in clever ways to also reduce bias. In certain cases, observational data can produce compelling evidence of cause and effect.

Observation vs. Experimentation

- Suppose we are interested in whether a certain surgical procedure prolongs life in cancer patients:

- What is disease severity in this directed acyclic graph (DAG)?
- How does this DAG change if the surgical procedure is randomly assigned?

Lurking variables a.k.a. confounders

- The textbook talks about lurking variables. These are what we refer to as confounders
- Confounders are only important if you are asking a causal/etiologic question.
- **There are no confounders in a predictive or descriptive study**

Other ways exposure is assigned

- **Pre and post studies:** In these studies the health outcome of interest is measured before and after some exposure (say, a policy change) is introduced. However, if there are any other changes over time that affect the health outcome, then comparing the health outcome in the pre- vs. post- period will be biased by these other changes over time. For example, you might look at the rate of handwashing at a hospital before and after an intervention was introduced to increase handwashing.
- **Natural experiments:** In a natural experiment, there is a shock that leads to an abrupt change to an exposure. This shock is thought to be unrelated to anything else happening (this can be examined). For example, you might look at how a heatwave event impacts adult mortality.
- **Randomized roll out (stepped wedge design):** This design is a type of randomized trial. Rather than randomizing half to receive treatment and the half to receive placebo, the experimenter randomizes clusters to receive the treatment at different points in time.

Population of interest

Target Population

- The target population is the entire group of individuals who we want information, and to whom we would like to apply the estimates and conclusions.
- Identifying the target population is part of setting up the “Problem” in the PPDAC framework

Study population

The study population is the part of the population that you can draw a sample of individuals from.

Study sample

The study sample is composed of individuals who have been sampled from the study population. This is the group on which you gather data. Samples are used to draw conclusions about the target population.

Example: Predictors of longevity

Study of interest: Brandts L, van den Brandt PA. Body size, non-occupational physical activity and the chance of reaching longevity in men and women: findings from the Netherlands Cohort Study. J Epidemiol Community Health. Published Online First: 21 January 2019

From the abstract:

Introduction: The rising number of obese and/or physically inactive individuals might negatively impact human lifespan. This study assessed the association between height, body mass index (BMI) and non-occupational physical activity and the likelihood of reaching 90 years of age, in both sexes separately.

Methods: Analyses were conducted using data from the Netherlands Cohort Study. The NLCS was initiated in 1986 as a large prospective cohort study and included 120,852 men and women aged 55–69 years from 204 Dutch municipalities. Participants born in 1916–1917 (n=7807) completed a questionnaire in 1986 (at age 68–70 years) and were followed up for vital status information until the age of 90 years (2006–2007).

Example: Predictors of longevity

Thinking about this abstract,

- Who composes the target population?
- Who is in the study sample?
- To whom might we be trying to generalize these results?

Study design: Sampling

How is the sample chosen from the population? This is part of the “Plan” part of PPDAC.

- When you are designing a study you need to decide how you will sample individuals:
 - Decide who belongs to the target population
 - Decide how you will identify the study population (sometimes called identifying a sampling frame)
 - Decide how you will take a sample of the study population. Or whether you can gather data on everyone like in a census
 - Decide how many people to sample
- Think about what you want your data frame to look like.

Representative(ness)

- Does the sample represent a population of interest? Can we make conclusions based on the sample that will apply to another population?
- Representativeness is also called **external validity**.
- For example, you may conduct a study in the United States and publish the research. People who read this research may be in Canada, or Mexico, or on another continent. They’ll want to know if your results can generalize to their settings or if the results are expected to be different in their contexts. This is hard to know and depends on the particular research question.

Study samples that generally do not give representative samples

The following types of studies do not generally give representative samples:

- 1) **Non-probability designs:** these are designs in which individuals are not randomized to receive the treatment or exposure. Some examples include:
 - **Case series:** A few selected individuals are studied in depth and described. Case series are important when a new or rare health condition occurs so that information about the emerging or rare condition can be communicated to the larger medical field.
 - **Convenience samples:** Convenience samples are composed of individuals who it is convenient to sample, like students near you on campus.
 - **Voluntary response samples:** Voluntary samples are samples in which many individuals are invited to respond (who is invited is non-randomized) and a subset chooses to respond. Many internet polls use voluntary response.

More representative designs: Probability samples

- Simple random sample (SRS): A sample where each individual in the data set has the same chance of being selected.
- We can easily choose a SRS from a data frame in R and we will learn how to do this in the next class.

Study design: Data collection

Study design: Data collection

- Part of your study design is about how you will collect data on the variables of interest:
 - By survey? (Self-reported information)
 - Measured using a device?
 - Collected from previously recorded information in health records?
- What are the types of variables and levels of each variable?
 - Continuous?
 - Categorical? How many categories? Ordinal or nominal?
- Think about what the data frame will look like. Ideally, we want the data frame to be rectangular like all the ones we have used in class. Often, we will have one row of data per sampled individual. Sometimes you will have multiple rows of data per person if data is collected on each person at multiple time points. Here, you have one row of data per person-visit (e.g., row 1: person 1, visit 1; row 2: person 1, visit 2, etc.)

Temporality

Temporality

- Method and timing of data collection
 - Cross sectional: Data is collected from one point in time only on both the exposure and the outcome variable.
 - Longitudinal: Data is collected at multiple timepoints. For example, you could measure someone's exposure to a pharmaceutical drug across several years to study the possible long term effects of exposure on an outcome of interest.
 - Prospective: In a prospective study, you plan the study first and collect data going forward in time.
 - Retrospective: In a retrospective study, you plan a study and then look back to collect the data from previous times

Putting it together

Read the following article titles. What do the titles tell you about the design? What do they tell you about what the target population might be? What would you ask about the methods?

These articles are from the American Journal of Epidemiology Volume 188, Issue 2, February 2019:

- 1) Associations of a Healthy Lifestyle Index With the Risks of Endometrial and Ovarian Cancer Among Women in the Women's Health Initiative Study
- 2) Death and Chronic Disease Risk Associated With Poor Life Satisfaction: A Population-Based Cohort Study

This article is from New England Journal of Medicine 2019; 380:415-424

- 1) Partial Oral versus Intravenous Antibiotic Treatment of Endocarditis: A randomized, noninferiority, multicenter trial
